Assessment of SARS-CoV-2 Reinfection 1 Year After Primary Infection in a Population in Lombardy, Italy

Despite more than 150 million people becoming infected worldwide, SARS-CoV-2 reinfections are uncommon. The risk of a

Editor's Note [page 1409](#)

[Supplemental content](#)

The rate of reinfection among health care workers has been reported,^{1,2} but the rate of reinfection in the general population is less clear.^{3,4}

Methods | We investigated the incidence of SARS-CoV-2 primary infection and reinfection among individuals who, during the first wave of the pandemic in Italy (February to July 2020), underwent diagnostic reverse-transcriptase-polymerase chain reaction (PCR; see eAppendix in the [Supplement](#) for the platform and specifics). Symptomatic and asymptomatic patients of any age, who were recruited in several screening and contact-tracing programs, were in-

cluded. We obtained the approval of the local ethics committee, which, because of the observational characteristic of the study, granted a waiver of informed consent for participants. This study followed the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) reporting guideline for cohort studies.

The study laboratory serves 4 hospitals (1400 beds) and one of the most severely affected sanitarian areas (560 Km²; 470 000 inhabitants) in Lombardy, Italy, yielding 122 007 PCR test results. We defined cases (those with infection who were PCR-positive) and controls (those without infection who were PCR-negative) according to the World Health Organization guidelines; criteria are specified in eAppendix in the [Supplement](#). The cohorts were considered to be at risk from the time of the first definition (date of positive test result for cases; date of second negative test result for controls) until the end of the observation (February 28, 2021) or a new positive PCR test result. Reinfections were defined by a second RT-PCR positivity beyond 90 days after complete resolution of the first infection and with at least 2 consecutive negative test results between episodes.⁵ The 90-day window was decided on the basis of reports of RNA virus persistence until 12 weeks.⁵ Statistical analyses were conducted using JMP, version 14.0 (SAS Institute), and Prism, version 9.0.2 (GraphPad). Statistical significance was set at $P < .05$.

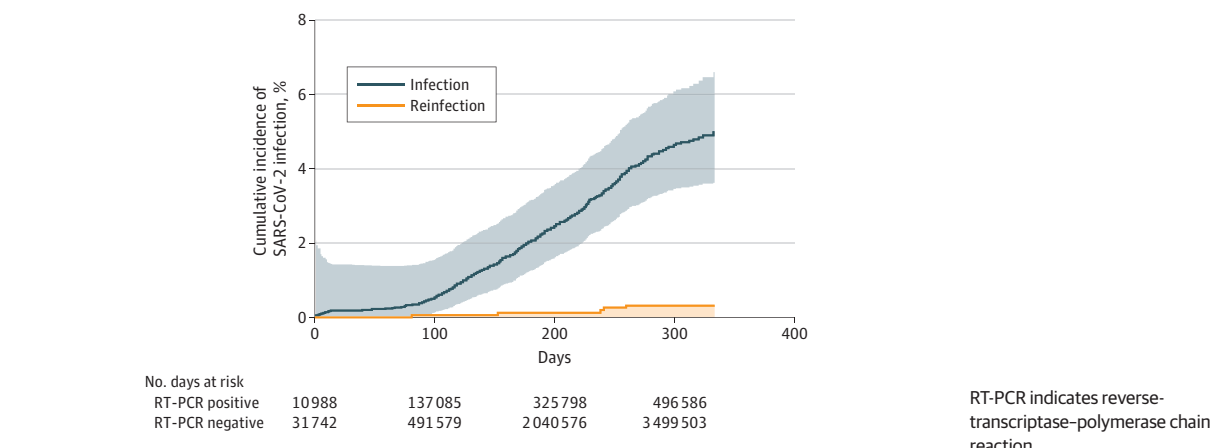

Results | The baseline demographic characteristics are shown in the [Table](#). The median (interquartile range) age of the pa-

Table. Population Characteristics

Characteristic	SARS-CoV-2 RT-PCR		
	Negative result at baseline and during follow-up (n = 12 968)	Negative result that converted to positive during follow-up (n = 528)	Positive result at baseline (n = 1579)

Figure. Cumulative Incidence of SARS-CoV-2 Infection

tients was 59 (40-78) years, but positive cases were older and geographically distributed more in the industrial area of Legnano.

During the follow-up (mean [SD], 280 [41] days) 5 reinfections (0.31%; 95% CI, 0.03%-0.58%) were confirmed in the cohort of 1579 positive patients. Most of these patients were evaluated, treated, and followed in hospitals or dedicated COVID-19 ambulatories.⁶ Only 1 was hospitalized, and 4 patients had a close relationship (2 patients work in hospitals, 1 patient underwent transfusions every week, and 1 patient retired in a nursing home) with health facilities. The mean (SD) interval between primary infection and reinfection was longer than 230 (90) days.

Of 13 496 persons who initially were not infected with SARS-CoV-2, 528 (3.9%; 95% CI, 3.5%-4.2%) subsequently developed a primary infection. The incidence density per 100 000 person days was 1.0 (95% CI, 0.5-1.5) for reinfections compared with 15.1 (95% CI, 14.5-15.7) for new infections, while the incidence rate ratio adjusted for age, sex, ethnicity, and the sanitarian area was 0.07 (95% CI, 0.06-0.08). After analyzing the cumulative incidence during follow-up, we confirmed that the 2 cohorts were significantly different (hazard ratio, 0.06; 95% CI, 0.05-0.08; log-rank test $P < .001$) (Figure).

Discussion | The study results suggest that reinfections are rare events and patients who have recovered from COVID-19 have a lower risk of reinfection. Natural immunity to SARS-CoV-2 appears to confer a protective effect for at least a year, which is similar to the protection reported in recent vaccine studies. However, the observation ended before SARS-CoV-2 variants began to spread, and it is unknown how well natural immunity to the wild-type virus will protect against variants.

Editor's Note

Protection Because of Prior SARS-CoV-2 Infection

How much protection against future infections does prior infection with SARS-CoV-2 infection provide? This is an important question for advising individual patients, as well as for projecting future outbreaks of SARS-CoV-2.

In this issue of *JAMA Internal Medicine*, Vitale and colleagues¹ use the results of diagnostic reverse-transcriptase-polymerase chain reaction tests in Lombardy, Italy, to compare the incidence of SARS-CoV-2 infection among persons with prior SARS-CoV-2 infection with persons who tested negative for the virus.

The differences were dramatic. The incidence density per 100 000 person days was 1.0 (95% CI 0.5-1.5) for persons with a history of infection and 15.1 (95% CI, 14.5-15.7) for persons without a history of infection. These results complement those of Harvey and colleagues² from the US, who found that patients with a positive diagnostic nucleic acid amplification test result for antibodies to SARS-CoV-2 were much less likely to develop SARS-CoV-2 infection at 90 days than persons without antibodies.

Before assuming that people with documented SARS-CoV-2 infections, whether by polymerase chain reaction diagnostic testing or by presence of antibodies, are protected against future infections, there are 2 caveats. First, we do not know how long natural immunity lasts. Second, we do not know if natural immunity to the wild-type virus is equally protective for SARS-CoV-2 variants (viruses with genetic variations). As has been indicated by Spellberg and colleagues,³ achieving herd immunity through natural infection is a long and painful process, and, historically, the only human disease to be eradicated, smallpox, was eradicated through vaccination, not natural infection.

Because it is likely that immunization plus history of natural infection is better protection than natural infection alone, all persons should be encouraged to get vaccinated even if they have been previously infected with SARS-CoV-2. Although unproven, it is possible that vaccination provides broader immunity to variants than natural infection. And because we do not know how long vaccine protection will last or whether there will be variants that escape protection from vaccination, we may need immunization boosters and or reformulated vaccinations in the future.

Assessment of FDA Approval for New High-risk Therapeutic Devices Not Meeting Pivotal Study Primary End Points, 2016-2020

The US Food and Drug Administration (FDA) regulates high-risk medical devices through the premarket approval (PMA) pathway. To obtain FDA approval, manufacturers typically must conduct a pivotal premarket study providing evidence of device safety

Supplemental content

and effectiveness.¹ The FDA assesses device risks and benefits as measured in pivotal studies by primary end points, such as the magnitude of clinical symptom improvement or occurrence of adverse events.¹ However, the FDA recently approved a temporary cardiac support device for use during high-risk percutaneous coronary interventions despite early termination of its pivotal study owing to futility.² In this cross-sectional study, we sought to systematically determine the frequency of, and rationale for, FDA approval of high-risk therapeutic medical devices not meeting pivotal study primary end points.

Methods | Using the FDA PMA database,³ we conducted a retrospective cross-sectional analysis of new high-risk therapeutic medical devices approved between January 1, 2016, and December 31, 2020 (eFigure in the Supplement). In accordance with previously described methods,⁴ we reviewed FDA summary documents to identify all pivotal studies evaluating these devices and their primary end points. We then determined which studies did not meet at least 1 prespecified primary end point.

For each device not meeting a pivotal study primary end point, we extracted device, pivotal study, and primary end point characteristics (eMethods in the Supplement). We also determined the FDA-provided rationale for approval and whether a postmarket study was mandated as a condition of approval.³

All search results were current as of March 7, 2021. All data were summarized with descriptive statistics using Excel for Mac, version 16.49 (Microsoft). This study used public, non-identifiable data that did not constitute human participants research (45 CFR 46.102) and was not submitted for institutional review board review.

Results | Between January 1, 2016, and December 31, 2020, the FDA approved 107 new high-risk therapeutic medical devices, of which 14 (13.1%) did not meet at least 1 pivotal study primary end point. Among these devices, 10 were cardiovascular, 4 were life sustaining, and 11 were implantable (Table 1).

In 15 pivotal studies, the 14 devices did not meet 16 of the 36 (44.4%) primary end points; 3 devices did not meet all of the primary end points, 10 devices did not meet an effectiveness end point, and 2 did not meet a composite safety-effectiveness end point. Seven devices were assessed against a comparator, and 7 were assessed against other criteria (eg, performance goals). Three devices did not meet noninferiority end points, and 6 did not meet surrogate end points. The FDA frequently cited post hoc analysis, success of other primary end points, and positive trends in secondary or nonprespecified outcome measures as rationales for approval (Table 1). For 11 devices, the agency required at least 1 postapproval study.
